

July 2022 Sea Ice Outlook Key Statements

Contributor	Model Type	Model Name	Arctic Extent	Median	Standard Deviation	Low Error Bound	High Error Bound	Antarctic Extent	Alaska Extent	Maximum Alaska Extent	Uncertainty Estimate Summary	Pan-Arctic Sea Ice Extent Anomaly	Executive Summary	Method Summary	Sea Ice Concentration Data	Sea Ice Thickness Data	Post-Processing Description
Climate Prediction Center	Dynamic Model	Whole Model: CFSv2 Atmospheric component: NCEP GFS Oceanic component: GFDL MOM5	4.64	4.67	0.2	4.27	4.94		0.8	3.97	The uncertainty estimate is calculated from the 20-member ensemble.		The forecast is based on an initialized fully coupled system. Contributing factors include initial oceanic, sea ice and atmospheric conditions, with initial sea ice thickness being the dominant factor.	The outlook is produced from the Climate Prediction Center Experimental sea ice forecast system (CFSv2). The forecast is initialized from the Climate Forecast System Reanalysis (CFSR) for the ocean, land, and atmosphere and from the CPC sea ice initialization system (CISIS) for sea ice. Twenty forecast members are produced. Model bias that is removed is calculated based on 2007-2021 retrospective forecasts and corresponding observations.	NASA Team Analysis from NSIDC	CPC sea ice initialization system (CISIS)	Twenty forecast members are produced. Model bias that is removed is calculated based on 2007-2021 retrospective forecasts.
CPOM UCL (Gregory et al)	Statistical/ML	NA	4.68		0.32	4.36	5		0.57	4	Forecasts are Gaussian distributions. Forecast represents the mean, and uncertainties are given by the standard deviation	0.47	This statistical model computes a forecast of pan-Arctic September sea ice extent. Monthly averaged June sea ice concentration fields between 1979 and 2022 were used to create a climate network (based on the approach of Gregory et al 2020). This was then utilized in a Bayesian Linear Regression in order to forecast September extent. The model predicts a pan-Arctic extent of 4.68 million square kilometers. Sea ice concentration data were taken from NSIDC (Cavalieri et al., 1996; Maslanik and Stroeve, 1999)	Monthly averaged June sea ice concentration (SIC) data between 1979 and 2022 were used to create a June SIC climate (complex) network. Individual SIC grid cells were first clustered into regions of spatio-temporal homogeneity by using a community detection algorithm (see Gregory et al. 2020). Links between each of these network regions (covariance) were then passed into a Bayesian Linear Regression to derive an estimate on the prior distribution of the regression parameters. Subsequently a posterior distribution of the regression parameters was then derived in order to generate the forecast of September sea ice extent.	N/A	N/A

University of Washington/APL	Dynamic Model	Pan-Arctic Ice-Ocean Modeling and Assimilation System (PIOMAS, Zhang and Rothrock, 2003), with coupled sea ice and ocean model components. The ocean model is the POP (Parallel Ocean Program) model and sea ice model is the thickness, floe size, and enthalpy distribution (TFED) model (Zhang et al., 2016). Atmospheric forcing is from the NCEP Climate Forecast System (CFS) version 2 (Saha et al., 2014) hindcast and forecast. To obtain the "best possible" initial ice-ocean conditions for the forecasts, we conducted a retrospective simulation that assimilates satellite ice concentration and SST data through the end of June 2022 using the CFS hindcast forcing data. We also assimilated CryoSat2 ice thickness available up to April 2020.	3.96		0.4								Driven by the NCEP CFS forecast atmospheric forcing, PIOMAS is used to predict the total September 2022 Arctic sea ice extent as well as ice thickness field and ice edge location, starting on July 1. The predicted September ice extent is 3.96±0.40 million square kilometers. The predicted ice thickness fields and ice edge locations for September 2022 are also available (see attachment).	The PIOMAS forecasting system is based on a synthesis of PIOMAS, the NCEP CFS hindcast and forecast atmospheric forcing, satellite observations of ice concentration and sea surface temperature (SST), and CryoSat2 observations of sea ice thickness.	Initial SIC is from PIOMAS hindcast that also assimilates satellite SIC (NASA team) available from NSIDC (https://nsidc.org/data/nsi00001).	Initial SIT is from PIOMAS hindcast that also assimilates CryoSat2 SIT data up to April 2020 (http://psc.apl.uw.edu/sea_ice_csr/).	
HEU Group (Zhao, et al)	Statistical/ML	NA	4.48					18.27					The outlook is based on two statistical methods: climate trends regression prediction and previous bias correction. Based on the consensus that arctic sea ice is significantly decreasing, we calculate the trend of sea ice concentration in each grid in the Arctic region and then use this trend to predict the value of sea ice concentration in that grid this year. The satellite observation data of this year before the prediction are used to calculate the real change of this year, and further correct the change trend obtained by the regression of climate trend. This is the meaning of the previous bias correction. By combining the above two methods, a more reasonable distribution field of sea ice concentration is obtained, and then the sea ice extent is calculated.	When obtaining the regression prediction results of climate trend, we used the NSIDC-0051 sea ice concentration dataset of NSIDC NASA TEAM algorithm, with a time range of 1989-2020 and a spatial resolution of 25km. Firstly, we calculated the linear regression coefficients of each grid during 1989-2020. The trend of climate change in the grid is analyzed, and the sea ice concentration of each grid in 2022 is calculated by using the linear regression coefficient. In the previous bias correction part, we also used the value of sea ice concentration from January to May 2022 of NSIDC 0051, calculated the curve of sea ice extent retrieved by satellite from January to May 2022, and compared it with the change of sea ice extent from January to May 2022 predicted by climate trend regression. The average difference between the two was obtained as a basis for previous bias corrections, climate trend predictions for September 2022 were then revised to obtain the final results.	NSIDC NASA Team, https://nsidc.org/data/nsi00001 , https://nsidc.org/data/nsi00001	NA	
Simmons	Statistical/ML	NA	4.06		0.37						The uncertainty estimate is the error reported by the linear regression.	0.054	This year's Outlook of 4.06 MK ² is nearly the same as last year's estimate of 4.05 MK ² , and nearly the same as the outlook for the previous two years. This year, there is less northern hemisphere snow cover (5.51 MK ² vs 6.17) and slightly more CO ₂ (as usual), but June ice area is slightly higher than last year (8.6 vs 8.4).	This Outlook uses a linear regression of October Mean Sea Level CO ₂ concentration, June average arctic ice area (NSIDC), and June average northern hemisphere snow area (Rutgers Climate Lab) to predict September average sea ice extent. Looking at snow and ice areas is intended to estimate insulation that is being received in the arctic. Looking at CO ₂ concentrations is intended to estimate other heat in the system.	NA	NA	
Cawley, Gavin	Statistical/ML	NA	4.21159	4.21159		3.0926	5.3305				Uncertainty estimate provided by Gaussian Process regression.		Simple Gaussian Process Regression of the September mean Arctic sea ice extent for previous years.	Simple statistical extrapolation of the sea ice extent from previous years, using a Gaussian Process model.	NA	NA	
Dmitri Kondrashov (UCLA)	Statistical/ML	NA	4.81		0.14				0.52		This uncertainty corresponds to standard deviation of stochastic ensemble spread.	0.4	This model forecast is based on statistical/ML stochastic modeling techniques applied to the regional Arctic Sea Ice Extent (SIE) dataset.	Statistical/ML stochastic modeling techniques have been applied to the regional Arctic Sea Ice Extent (SIE) from Sea Ice Index Version 3 dataset. The daily SIE data were aggregated to provide weekly-sampled dataset over several Arctic sectors. The predictive model has been derived from SIE anomalies with annual cycle removed, and is initialized from latest SIE conditions by ensemble of stochastic noise realizations to provide probabilistic regional Arctic forecasts in September.	NA	NA	
KOPRI (Chi et al.)	Statistical/ML	NA	5.05	5.01	0.16	4.82	5.35				We selected ten most accurate models in the training process and then use them for the uncertainty estimate.		KOPRI's prediction model uses the past 12-month data as inputs for the six-month predictions of Arctic sea ice concentration (SIC). The predicted September extent for 2022 is 5.05 million square kilometers using data from July 2021 to June 2022.	KOPRI's fully data-driven model was trained on historical NSIDC's daily SIC data from 1979 to 2021 using a combination of convolutional and recurrent neural networks. Since we observed a large visual discrepancy according to the neural network's bias functions, a new loss function was developed to improve both statistical accuracy and visual agreement. The 6-month prediction model is currently being tuned up to improve predictability. Please find our recent published paper: Chi J, Eae J, Kwon Y. Two-Stream Convolutional Long- and Short-Term Memory Model Using Perceptual Loss for Sequence-to-Sequence Arctic Sea Ice Prediction. Remote Sensing. 2021; 13(17):3413. https://doi.org/10.3390/rs13173413	NSIDC NASA Team, https://nsidc.org/data/nsi00001 , https://doi.org/10.5067/8Q8LZ0VL0VL , https://nsidc.org/data/nsi00001 , https://doi.org/10.5067/7TTH02FJ097K	NA	Negative SIC predictions over ocean pixels were set to 0% and SIC predictions over 100% were set to 100%. We also used land and coastline masks from NSIDC's SIC data
NCEP-EMC (Wu et al.)	Dynamic Model	a) Model Name: NCEP CFSv2 b) Component Name Initialization Atmosphere NCEP GFS NCEP CDAS Ocean GFDL MOM5 NCEP GCOMS ICE Modified GFDL SIS SIC nudging c) 244 ensemble members (May 1-June 30 2022, each day from 4 cycles)	4.71		0.48			19.15					The projected Arctic minimum sea ice extent from the NCEP CFSv2 model May-June initial conditions (ICs) using 244-member ensemble forecast (4 cycles each day May 1 to June 30) is 4.71 million square kilometers with a standard deviation of 0.48 million square kilometers. The corresponding number for the Antarctic (maximum) is 15.15 million square kilometers with a standard deviation of 0.87 million square kilometers.	We used the NCEP CFSv2 model with 244-cycle of May-June 2022 initial conditions (4 cycles each day June 1-30) and model (bias-corrected for the Arctic).	NCEP Sea Ice Concentration Analysis for the CFSv2 (May 1-June 30, 2022)	NCEP CFSv2 model guess (May 1-June 30, 2022)	

Met Office	Dynamic Model	Model: HadGEM3 (Hewitt et al., 2011). Global Coupled Model 3.2 (Williams et al., 2018) in use within the GloSea6 seasonal prediction system. The model configuration has been updated, but all other details of the system (forecast members, hindcast members, anomaly calculations) are as described in MacLachlan et al. (2015). Sea ice component: CICE5.1 (Hunke et al., 2015) model using Global Sea Ice 8.1 configuration (Riley et al., 2018). Initialised using the Met Office FOAM ocean and sea ice analysis (Blockley et al., 2014), which assimilates the SSM/SeaWiFS sea ice concentration observation product from EUMETSAT OSI-SAF. Ocean component: NEMO (Madec, 2016) ocean model using Global Ocean 6.0 configuration (Storkey et al., 2018). Initialised using Met Office FOAM ocean and sea ice analysis (Blockley et al., 2014) assimilating in situ and satellite observations of SST (HRSS2), satellite observations of sea level anomaly (AVISO/CLS) and temperature and salinity sub-surface profiles. Atmosphere Component: Met Office Unified Model (MetUM) (Brown et al., 2012) using Global Atmosphere 7.2 configuration (Walters et al., 2019). Initialised using Met Office operational numerical weather prediction (NWP) 4D-Var data assimilation system (Rawlins et al., 2007). Land Component: Joint UK Land Environment Simulator (JULES) (Best et al., 2011) using Global Land 7.0 configuration (Walters et al., 2019). Soil temperature, soil moisture, and snow over land are initialised from running the land surface model forced with the JRA-55 analysis. Coupling: Ocean and sea ice are hard coupled. Atmosphere and land are hard coupled. The combined ocean/ice and atmosphere/land configurations are coupled using the OASIS3 coupled (Valke et al., 2015).	4.1	0.25	3.6	4.6	17.8			Uncertainty range is provided as +/- 2 two standard deviations of the 42 member ensemble spread around the ensemble mean.	A dynamic model forecast made using the Met Office's seasonal forecasting system (GloSea). GloSea is a fully coupled Atmosphere-Ocean-sea Ice-Land (AOIL) model that produces a small 2-member ensemble of 210-day forecasts each day. Forecasts initialised over a 21-day period are used together to create a 42-member lagged ensemble or forecasts of September sea ice cover.	Ensemble coupled model seasonal forecast from the GloSea6 seasonal prediction system based on MacLachlan et al., 2015), using the Global Coupled 3 (GC3) version (Williams et al., 2018) of the HadGEM3 coupled model (Hewitt et al., 2011). Forecast compiled together from forecasts initialised between 21 June and 1 July (2 per day) from an ocean and sea ice analysis (FOAM/NEOVAR) (Blockley et al., 2014; Peterson et al., 2015) and an atmospheric analysis (ECMWF/IFS) (Rawlins et al., 2007) using observations from the previous day. Special Sensor Microwave Imager Sensor (SSMIS) ice concentration observations from EUMETSAT OSI-SAF (OSI-SAF) were assimilated in the ocean and sea ice analysis, along with satellite and in situ SST, sub surface temperature and salinity profiles, and sea level anomalies from altimeter data. No assimilation of ice thickness was performed.	Sea ice concentration (as all variables) is initialised using the operational FOAM ocean-sea ice analysis. SSMIS sea ice concentration is assimilated using the EUMETSAT OSI-SAF (OSI-401b). See http://osistat.met.no/docs/osistat_cdo3_s2_pum_ice-conc_v1p6.pdf	Sea ice thickness (as all variables) is initialised using the operational FOAM ocean-sea ice analysis. Sea ice thickness is not assimilated in FOAM.	Bias correction in each hemisphere, calculated by evaluation of hindcasts over 1993-2016. Bias correction calculated from hindcast evaluation over 1993-2016. Arctic: 2.7 million sq. km. Antarctic: -0.3 million sq. km
METNO-SPARSE-ST (Wang et al.)	Statistical/ML	NA	4.524	4.524	0.225	4.974	4.074	17.595	0.54	95% confidence	AR model using NSIDC sea ice concentration data	AR model using NSIDC sea ice concentration data	NA	NA	
CPOM	Statistical/ML	NA	4.5		0.5					Mean forecast error based on forecasts for the years 1984 to 2021.	We predict the September ice extent 2022 to be 4.5 (±0.5) million km2. This is 0.3 million km2 above the trend line.	n/a	n/a	See references above	
UKMO-OIT	Heuristic	NA	4.25		0.44	3.37	5.13			Uncertainty range is provided as +/- 2 two standard deviations of all the individual guesses/contributions.	Adapted from a poll of scientists attending the Met Office internal ocean and sea ice seminar series in June 2022.	NA	NA		
EMC/NCEP (UFS)	Dynamic Model	a) Model Name: NCEP UFS b) Component Name: Initialization Atmosphere NCEP GFS/FV3 NCEP CDAS Ocean GFDL MOM6 NCEP GODAS ICE CICE5 GPC CSIS c) 14 ensemble members (May 3-9 and June 3-9 2022, each day 00Z with C192)	5.1		0.37		18.42			The projected Arctic minimum sea ice extent from the NCEP Unified Forecast System (UFS) model (May-June initial conditions (ICs)) using 14-member ensemble forecast (00Z May 3-9 and June 3-9 with C192) is 5.10 million square kilometers with a standard deviation of 0.37 million square kilometers. The corresponding number for the Antarctic (maximum) is 18.42 million square kilometers with a standard deviation of 0.32 million square kilometers.	We used the NCEP UFS model with 14-case of May and June 2022 initial conditions (May 3-9 and June 3-9 with C192) and bias-corrected for the Arctic.	NASA Team Analysis from NSIDC (May 3-9 and June 3-9, 2022)	CPC sea ice initialization system (CSIS) (May 3-9 and June 3-9, 2022)		
NSIDC (Meier)	Statistical/ML	NA	4.65		0.51		17.25			The uncertainty is based on the standard deviation of the projections from all of the years, 2007-2021.	This method applies daily ice loss rates to extrapolate from the start date (July 1) through the end of September. Projected September daily extents are averaged to calculate the projected September average extent. Individual years from 2005 to 2021 are used, as well as averages over 1981-2010 and 2007-2021. The 2007-2021 average daily rates are used to estimate the official submitted estimate. The predicted September average extent for 2022 is 4.55 (±0.51) million square kilometers. The minimum daily extent is predicted to be 4.53 (±0.50) million square kilometers and occurs on 16 September. The large range of estimates reflects the large variability in ice loss rates over the final 3+ months of the melt season. Based on the last 17 years (2005-2021), there is a 0% chance that 2022 will be lower than the current record low September extent of 3.57 million sq km in 2012. Using the same method, the predicted Antarctic average extent for September 2022 is 17.25 (±0.55) million square kilometers. The maximum daily extent is predicted to be 17.33 (±0.54) million square kilometers and occurs on 26 September.	This method applies daily ice loss rates to extrapolate from the start date (July 1) through the end of September. Projected September daily extents are averaged to calculate the projected September average extent. Individual years from 2005 to 2021 are used, as well as averages over 1981-2010 and 2007-2021. The 2007-2021 average daily rates are used to estimate the official submitted estimate. The method essentially provides the range of September extents that can be expected based on how the ice has declined in past years, though it is possible that record fast or slow daily loss rates may yield a value outside the projected range. It also can provide a probability of a new record by comparing how many years of loss rates yield a record relative to all years. It has the benefit that it can easily and frequently (daily if desired) be updated to provide updated estimates and probabilities and as the minimum approaches the "window" of possible outcomes narrows.	NASA Team algorithm extents from the NSIDC Sea Ice Index, Version 3 (http://nsidc.org/data/seaice_index/)	NA	
FIO-ESM (Shu et al.)	Dynamic Model	FIO-ESM1.0 Atmosphere CAM5 2000-2022 integration Ocean POP2 ocean data assimilation Ice CICE4 sea ice data assimilation Wave MANSUM-wave model 2000-2022 integration	4.01							Our prediction is based on FIO-ESM (the First Institute of Oceanography/Earth System Model) with data assimilation. The prediction of September pan-Arctic extent in 2022 is 4.01 (±0.18) million square kilometers. 4.01 and 0.18 million square kilometers is the average and one standard deviation of 10 ensemble members, respectively.	Our prediction is based on a climate model named FIO-ESM v1.0 (Qiao et al., 2013). Ocean and sea ice data are assimilated to initialize the model (Chen et al., 2016; Shu et al., 2021). The system bias was removed to get bias-corrected pan-Arctic September monthly-mean sea ice extent. The system bias is the mean error between reforecast sea ice extent and satellite derived sea ice extent during 2000 to 2009.	OSISAF, OSI-430-b, https://osistat.met.no/docs/osistat_cdo3_s2_pum_ice-conc_v1p6.pdf	PIOMAS, http://psc.apl.uw.edu/nese-arc/pjocets/arcic-sea-ice-volume-anomaly/data/model_grid		
MetService (Yizhe Zhan)	Statistical/ML	NA	5.1	0.3		4.8	5.4			The uncertainty range is estimated from the standard error of the correlation between June TOA-RSR and September SIE.	Our prediction is based on the strong correlation between detrended June top-of-atmosphere (TOA) reflected solar radiation (RSR) and September Sea Ice Extent (SIE) anomalies, as proposed by Zhan and Davies [2017]. This method is telling because the main contributor of TOA RSR anomaly in June is from the change of underlying surfaces and the sea ice state in early summer (June) largely determines the total absorbed shortwave solar radiation during the whole melt season.	Our contribution is formulated by adding the main contribution part from the September SIE trend (2002-2021) with the anomalous part from the June TOA-RSR (2022) anomaly. The detailed description of the calculation is as follows: 1. Calculate the detrended pan-Arctic June RSR anomaly (2022): 11.89 W/m2. 2. Estimate the corresponding September SIE anomaly: 0.91 (11.89 * 0.0765) million km2. 3. Calculate the trending anomaly of September SIE: -0.07 million km2 per year. 4. Calculate the 2022 September SIE (from the trending line): 4.19 million km2. 5. Estimate the predicted September SIE of 2022: 5.10 (4.19 + 0.91) million km2. Note that the coefficient of 0.0765 is estimated from the detrended anomalies of June TOA-RSR and September SIE between 2002 and 2021.	NA	NA	

AWI Consortium	Dynamic Model	NAOSIM v36, 14 degree, parameter optimized (optP3)	4.76	0.33											Ensemble spread	Forced sea ice - ocean model initialized in March and April with satellite products. Ensemble forecast is generated by using the forcing from ten previous years. Prediction potential comes from the initialization in March and April with satellite observations (sea ice thickness, snow depth, SST, and sea ice concentration). Deliberately no observations are assimilated later in the year because the potential of state estimation in March and April with respect to summer sea ice conditions should be evaluated.	For the present outlook the coupled sea ice-ocean model NAOSSIM has been forced with atmospheric surface data from January 1948 to July 5th 2022 (combination of NCEP-CFSR and NCEP-CFSv2). All ensemble model experiments have been started from the same initial conditions on July 5th 2022. The model setup is identical to the SIO 2019-2021 setup - a forecasting model (about 25km horizontal resolution) with optimized parameters (with the help of a genetic algorithm (Sumata et al. 2019, https://doi.org/10.1175/MWR-D-18-0360.1)) is employed. We used atmospheric forcing data from each of the years 2012 to 2021 for the ensemble prediction and thus obtain 10 different realizations of potential sea ice evolution for summer 2022. The use of an ensemble allows to estimate probabilities of sea-ice extent predictions for September 2022. A variational data assimilation system around NAOSSIM is applied to initialize the model using the Alfred Wegener Institute's CryoSat-2 ice thickness product, University of Bremen's snow depth and the OSI SAF ice concentration product 430b (interim Climate Data record). In contrast to previous years no sea surface temperature is assimilated due to the lack of these data streams. Observations from March and April were used. The assimilation system (Kauker et al. 2015, http://www.zoephep-geochem.net/2015/17/) is unchanged but no bias correction is applied any more to the CryoSat-2 ice thickness - this is not necessary anymore due to the optimization of the forecast model. UPenn-UQAM Group	Statistical/ML	NA	4.52	4.52	0.5	3.52	5.52									The UPenn-UQAM group is composed of economists and statisticians interested in predictive modeling of many aspects of climate in its relation to economic activity. The Arctic - and Arctic sea ice in particular - is of particular interest to us. As is well known, the Arctic is warming about twice as fast as the global average, and the Arctic amplification in surface air temperature is of course closely connected to the dramatic multi-decade reduction in Northern sea ice. This loss of sea ice is one of the most conspicuous warning signs of (current) climate change, and it also plays an integral role in the timing and intensity of (future) global climate change. Not surprisingly then, we are keenly interested in predictive modeling of Arctic sea ice, particularly summer ice.	We have supplied a forecast based on a statistical model with trend, a feed-forward loop, and stochastic shocks, estimated by direct projection. In the modeling process we explore different levels of aggregation of the underlying high-frequency (daily) concentration data and associated sea ice extent, and we tune the aggregation to optimize the predictive bias/variance tradeoff in forecasting September extent. It turns out that previous pseudo-out-of-sample forecast errors (residuals) are approximately Gaussian, which we exploit in making our out-of-sample forecast for this September. The predictive density is Gaussian, with the mean 4.52 million square kilometers and standard deviation of 0.5 million square kilometers. (By symmetry, the mean and median coincide.) The approximate 95% interval that we report is the mean plus or minus 2 standard deviations.	NA	NA	none
ANSO IAP-LASG	Dynamic Model	CAS-FGOALS-F2 (Atmospheric component: FAMIL2, Ocean component: POP, Sea ice component: CICE4, Land component: CLM4) Horizontal resolutions: Approximately 1° Initial methods: A nudging scheme to assimilate wind components (U and V), Temperature (T) in atmosphere and potential temperature in ocean	4.04	4.04	0.25	3.44	4.64									The prediction for the sea ice outlook July 2022 was carried out on China's Tianhe-2 supercomputer, with a dynamic model prediction system CAS FGOALS-F2 S2S V1.3. The dynamic model prediction system, named FGOALS-F2 (ice-ocean-atmosphere-land model), provides a real-time predictions in the subseasonal-to-seasonal (S2S) timescales. FGOALS-F2 S2S system has been established in 2017 by R&D team of FGOALS-F2 from both LASG Institute of Atmospheric Physics Chinese Academy of Sciences and PAEKU Chengdu University of Information Technology. The FGOALS-F2 S2S prediction results are used in three major national operational prediction centers in China. Based on the 4-month lead dynamic model prediction from July 12th, 2022 the outlook predictions of Sea Ice Extent are 4.04 million square kilometers for pan-Arctic in September 2022.	FGOALS-F2 S2S V1.3 is a global coupled dynamic prediction system. The initialization of this prediction system is based on a nudging scheme, which assimilates wind components (U and V), Temperature (T) in atmosphere and potential temperature in ocean from 1 Jan 1980 to 1 June 2019, and 48 ensemble members are generated by a time-lag method. The predictions are available here for 12 months. This real-time S2S prediction system is fully operated on China's Tianhe-2 supercomputer.	None	None	Model bias that is removed is calculated based on the retrospective forecasts and corresponding observations.
RASM@NPS (Maslowski et al.)	Dynamic Model	The version of Regional Arctic System Model (RASM v2_1_00) used for this contribution consists of the following components: Ocean: POP2.1 Atmosphere: WRF3.7.1 Sea-ice: CICE 5.1.2 Land hydrology: VIC 4.0.6 River streamflow routing: RVIC 1.1.0 Flux Coupler: CPL 7 This model initial condition for ensemble forecast was derived from a hindcast, forced with CFSR/CFSv2 reanalysis for September 1979 through May 2022. The ocean and sea ice initial conditions at the beginning of the hindcast were derived from the 32-year spin-up of the ocean-sea ice model only (RASM G-case) forced with CORE2 reanalysis for 1948-1979.	4.657	4.662	0.225	4.091	5.155	0.463	3.927							The Arctic sea ice extent September 2022 minimum is predicted to roughly continue the September declining trend (of 0.528x10 ⁶ km ² /decade) based on 2000-2021 output from the Regional Arctic System Model (RASM) hindcast simulation. The difference between the 30-member ensemble mean September sea ice extent prediction and the extrapolation 2000-2021 linear trend into 2022 is 0.104x10 ⁶ km ² . Compared to the RASM September 2021 sea ice extent minimum (4.695x10 ⁶ km ²) from the hindcast, the ensemble mean forecast for 2022 minimum is slightly lower by 0.038x10 ⁶ km ² , suggesting a continuous decline of sea ice after a brief rebound. According to the RASM ensemble mean predicted September sea ice thickness distribution, the majority of surviving ice thickness ranges between 1.0 m and 1.5 m, with the thickest sea ice north of the Canadian Archipelago and Greenland within the range of 1.5 m-2.5 m, and almost no sea ice thicker than 3.0 m (see Fig. 3 in the supplementary material). The RASM September outlook has been commonly biased high in recent years (bias of 0.07x10 ⁶ km ² and standard deviation of 0.415x10 ⁶ km ²) compared to the NSIDC observation (2000-2021), especially in the northern Barents/Kara and East Siberian seas.	We used RASM2_1_00, which is a recent version of the limited-area, fully coupled climate model consisting of the Weather Research and Forecasting (WRF), Los Alamos National Laboratory (LANL) Parallel Ocean Program (POP) and Sea Ice Model (CICE), Variable Infiltration Capacity (VIC) land hydrology and routing scheme (RVIC) model components (Maslowski et al. 2012, Roberts et al. or 2015, DuViver et al. 2015, Hamman et al. 2016, Hamman et al. 2017, Cassano et al. 2017). The model is forced with CFSR/CFSv2 reanalysis output for RASM/WRF lateral boundary conditions and for nudging winds and temperature starting about 500 mb for September 1979-June 2022. Then, RASM is used for dynamic down-scaling of the global NOAA-NCEP CFSv2 7-month forecasts. Each of the 30 ensemble members ran forward for 7 months using outputs from CFSv2 forecasts. The CFSv2 forcing (https://www.ncei.noaa.gov/data/climate-forecast-system/iceseas/forecast/1-month-forecast/) streams used for the ensemble members were initialized every day (at 00:00) between June 1st and June 30th and used for RASM forcing at 00:00 on July 1st, 2022 and onward until the end of December 2022.	The initial sea ice conditions for the June Sea Ice Outlook were derived from the RASM 1979-2022 hindcast and internally consistent across all the model components. Neither data assimilation nor bias correction was used.	See the above.	Daily mean sea ice with concentration <15% and thickness <- 20 cm was excluded in the estimates of September sea ice extent.
Sun	Statistical/ML	NA	5.26	0.3	4.72	5.57	18.24	0.6	4							Each grid-cell is initialized with a thickness derived from the AMSR2 Sea Ice Volume model (https://cryosphere.computing/MSIT/). For each day the model calculates average thickness per grid cell using the exact solar radiation energy and the predicted sea ice concentration as an abductive value. $ice_{loss(g)} = Energy_{solar} in MJ / (1-SIC) \cdot ice_{energy}$ $SIC = sea\ ice\ concentration$ $ice_{energy} = Melteneg\ per\ m3, (333.55\ KJ/kg / 1000(m3/dm^3) * 92(density) / 1000(MJ/KJ))$	The forecast model is based on ice persistence. It uses incoming solar radiation and sea ice albedo derived from a predicted Sea Ice Concentration (SIC) value to calculate daily thickness losses for every NSIDC 25km grid cell. The initial thickness is calculated from AMSR2 sea ice volume and NSIDC SIC data. Instead of a long-term mean, the 2022 model predicts SIC change based on correlation to previous years. A special formula calculates a best new mean field based on past years. Years with a very high correlation get weighted more. For this month the mean field is made up of: '2007,2007,2010,2010,2010,2013,2013,2013,2013' The mean forecast uses the SIC (1/4 weight) and mean SIC change per day (3/4 weight) to predict future SIC. The formula reduces the predicted SIC by 0.35tdv for previously observed SIC for this day and a 10% increased bottom melt. The high forecast increases the predicted SIC by 0.10stdv and a 10% decreased bottom melt. Since 2020 model includes a bias correction layer to reduce persistent errors of under prediction or over prediction based on past forecasts. This layer simulates ice drift or cold freezing off blowing from landmasses causing refreezing.	NSIDC NASA Team, https://nsidc.org/data/nsid0-0081, https://doi.org/10.5067/10.809D/VVXRLM. GFDL/NOAA, Bushuk et al.	Dynamic Model	Model: GFDL-SPEAR_MED Atmosphere AM4 Initialized from nudged atmosphere and SST run Land LM4 Initialized from nudged atmosphere and SST run Ocean MOM6 Initialized from EnKF coupled data assimilation Sea Ice SIS2 Initialized from nudged atmosphere and SST run	4.74	4.76	0.15	4.4	5	0.56	3.94	These statistics are computed using our 30 member prediction ensemble.	0.53	Our July 1 prediction for the September-averaged Arctic sea-ice extent is 4.74 million km ² , with an uncertainty range of 4.40-5.00 million km ² . Our prediction is based on the GFDL-SPEAR_MED ensemble forecast system, which is a fully-coupled atmosphere-land-ocean-sea ice model initialized using a coupled data assimilation system. Our prediction is the bias-corrected ensemble mean, and the uncertainty range reflects the lowest and highest sea ice extents in the 30-member ensemble.	Our forecast is based on the GFDL Seamless system for Prediction and Earth system Research (SPEAR_MED) model (Delworth et al., 2020), which is a coupled atmosphere-land-ocean-sea ice model. The ocean model is initialized from an Ensemble Kalman Filter coupled data assimilation system (SPEAR_ECDA; Lu et al., 2020), which assimilates observational surface and subsurface ocean data. The sea ice, land, and atmosphere components are initialized from a nudged ensemble run of the coupled SPEAR_MED model, which is nudged towards 3-D temperature, wind, and humidity data from CFSR and SST data from OISST. The SST values under sea ice are adjusted to the freezing point of sea water using OISST sea ice concentration data. The performance of this model in seasonal prediction of Arctic sea ice extent has been documented in Bushuk et al. (2022). For an evaluation of the model's September sea ice extent prediction skill from a July 1 initialization, see attached report.	OISST SIC data is used to correct assimilated SST values under sea ice.	No SIT data is explicitly used in our initialization procedure.	These forecasts are bias corrected based on a linear regression adjustment using a suite of retrospective forecasts spanning 1992-2021.
UQAM (VARCTIC)	Statistical/ML	NA	4.68	4.68		4.1	5.28			The lower bound constitutes the 5th percentile and the upper bound the 95th percentile of the credible region. Done via the posterior distribution obtained by standard Bayesian Methods for linear Vector Autoregressions.		When it comes to forecasting sea ice, there is tension between opting for statistical methods vs forecasts based on climate models. While the former are explicitly designed for the prediction task, they usually lack interpretative potential. That is, we may get a good forecast, but it is hard to know why. Institutions in charge of macroeconomic policy have been facing such dilemmas for years. One model, Vector Autoregressions, have been increasingly popular to forecast economic aggregates as they are a compromise between theory-based methods and statistical ones. As a result, it is possible to obtain an explainable forecast which are the results of dynamic interactions between key Arctic variables. Hence, our forecast implicitly uses physical transmission mechanisms in the data, without specifying them explicitly.	The VARCTIC, which is a Vector Autoregression (VAR) designed to capture and extrapolate Arctic feedback loops, VARs are dynamic simultaneous systems of equations, routinely estimated to predict and understand the interactions of multiple macroeconomic time series. Hence, the VARCTIC is a parsimonious compromise between full-blown climate model and purely statistical approaches that usually offer little explanation of the underlying mechanism. Precisely, we use an 8-variable Bayesian Vector Autoregression (VAR) with 12 lags and a constant which we refer to as the VARCTIC. We estimate the model over the period from January 1980 until February 2022. A detailed description can be found in the following paper: https://journals.ametsoc.org/view/journals/clim/34/13/JCLI-D-20-0324.1.xml	Fetterer, F., K. Knowles, W. N. Meier, M. Savoie, and A. K. Lamont (Yuan and Li)	Statistical/ML	NA	4.54	0.43		4.11	4.97	18.44	0.64	The Arctic SIE uncertainty is measured by RMSE between predicted and observed SIE.	0.33	A linear Markov model is used to predict monthly Arctic sea ice concentration (SIC) at all grid points in the pan-Arctic region (Yuan et al., 2016). The model has been retrained this month using SIC, atmosphere variables and SST from 1979 to 2021. The September pan-Arctic sea ice extent (SIE) is calculated from predicted SIC. The model predicts negative SIC anomalies throughout the pan-Arctic region. The September mean pan-Arctic SIE is predicted to be 4.54 million square kilometers (mskm) with an RMSE of 0.43 mskm based on model cross-validation experiments, at the three-month lead. The Alaskan regional SIE is predicted to be 0.64 mskm. A similar statistical model was also developed to predict the SIE in the Antarctic (Chen and Yuan, 2004). The September mean pan-Antarctic SIE is predicted to be 18.44 mskm, close to September 2021 (18.45), with an RMSE of 0.42 mskm. The RMSE is estimated based on our model forward forecasts from 2003-2020.	The linear Markov model has been developed to predict sea ice concentrations in the pan Arctic region at the seasonal time scale. The model employs 6 variables: NASA Team sea ice concentration, sea surface temperature (ERSST), surface air temperature, GH300, vector winds at GH300 (NCEP/NCAR reanalysis) for the period of 1979 to 2021. It is built in multi-variate EOF space. The model utilizes first 11 EOF modes and uses a Markov process to predict these principal components forward one month at a time. The pan Arctic sea ice extent forecast is calculated by summing up all cell areas where predicted sea ice concentration exceeds 15%.	Sea ice concentration: NSIDC NASA Team. https://nsidc.org/data/nsidc/c00901 ; https://doi.org/10.5067/78C09DWWX91M	NA	Bias corrections include constant bias corrections of SIC predictions at grid points, regression correction of SIE prediction and resolution corrections.
PoiArctic	Statistical/ML	NA	4.71							This is PoiArctic's fourth year submitting to the Sea Ice Outlook. Our September extent prediction is 4.71 million square kilometers. Our efforts are to investigate the usefulness of Artificial Intelligence and Machine Learning (AIML) as a predictive tool for Arctic sea ice extent. Hidden and non-linear relationships can be exposed through the use of AIML when high quality data is available. NSIDC's daily record of sea ice extent creates the perfect test bed to leverage and assess the power of AIML.	PoiArctic's September SIO extent was generated using our Artificial Intelligence algorithm, and trained with historical NSIDC daily ice extent data. Our initial modeling efforts are to generate high quality seasonal forecasts of daily, spatial and temporal sea ice extents. To calculate our September extent outlook, daily results in September 2022 from our model are averaged.	NOAA/NSIDC, Sea Ice Index, Version 3. https://doi.org/10.7755/NSIDC.5K072F8 .	NA			
ASIC, NIPR	Statistical/ML	NA	4.53							Monthly mean ice extent in September will be about 4.53 million square kilometers. Our prediction is based on a statistical way using data from satellite microwave sensor. We used two factors: sea ice redistribution from winter to spring and accumulated absolute value of sea ice divergence. Predicted ice concentration map from July 1 to September 20 is available in our website: https://www.nipr.ac.jp/sea_ice/forecast/2022-07-01-1/	We predicted the Arctic sea-ice cover from coming July 1 to September 20, using the data from satellite microwave sensors, AMSR-E (2002/03-2010/11) and AMSR2 (2012/13-2021/22). The analysis method is based on our research. The predictions were based on two factors: "sea ice redistribution from winter to spring," and "accumulated absolute value of sea ice divergence". The sea ice redistribution was determined from the sea ice movement from December to the end of May (Kimura et al., 2013), and the accumulated absolute value of the divergence was calculated from daily values for 90 days until the end of May. Then, we calculated the summer ice concentration by multiple regression analysis based on the two factors. The "accumulated absolute value of sea ice divergence" is an indicator of the ease of sea ice movement. In areas where this value is large, sea ice is expected to be thin and easy to melt, as it is easy for sea ice to move freely. On the other hand, areas where this value is small are covered by firm, thick sea ice and are less likely to melt.	10cm grid data distributed by Arctic Data archive System (https://ads.nipr.ac.jp)	NA			
Horvath, et al.	Statistical/ML	NA	4.97							Yearly data from 1980 through the present are used in a Bayesian logistic regression to predict the probability that sea ice concentration will be above 15%. To estimate total sea ice extent, grid cells with a percentage above a certain threshold (chosen from a drop-one cross-validation test) are multiplied by the pixel area grid dataset provided by NSIDC's polar stereographic toolset and then summed. Sea ice concentration data was obtained from NSIDC's Sea Ice Index V3 (Data Set ID: G02135), all other variables are from ERA5.	This statistical model computes the probability that sea ice will be present (concentration above 15%) for each grid cell in NSIDC's polar stereographic projection. Yearly data from 1980 through the present are used in a Bayesian logistic regression. Predictors include local surface air temperature, downwelling longwave radiation, and sea ice concentration, as well as the first principal component of geopotential height at 500hPa, and Pacific and Atlantic sea surface temperatures. Sea ice concentration data was obtained from NSIDC's Sea Ice Index V3 (Data Set ID: G02135), all other variables are from ERA5.	NA	NA			
NMEFC of China (Li and Li)	Statistical/ML	NA	4.76							We predict the September monthly average sea ice extent of Arctic by statistic method and based on daily sea ice concentration and monthly extent from National Snow and Ice Data Center. The predicted monthly average ice extent of September 2022 is 4.76 million square kilometers.	A simple statistical model is used to predict September average Arctic sea ice extent. The sea ice extent of September is well related with the sea ice extent of Jun in the same year. Combined the regression method and optimal climate normal method, the predicted September sea ice extent in 2022 is 4.76 million square kilometers.	Sea Ice Index - Daily sea ice concentration (NSIDC NASA Team) and monthly sea ice extent from NSIDC.
